# The Case For A Credit Registry

Atif Mian \*

April 2012

Abstract

<sup>\*</sup>I thank Asim Khwaja, Markus Brunnemeir, Arvind Krishnamurthy and participants at the NBER conference on Systemic Risk in New York for comments and suggestions. Special thanks to Ramón Santillán at Banco de España for answering questions concerning the design of credit registry systems. Funding from the Coleman Fung Risk Management Center at Berkeley is gratefully acknowledged. The author can be contacted at: Ph - (510) 643 1425. Email - atif@haas.berkeley.edu.

### 1 Introduction

The banking sector is often blamed for exposing the economy to systemically important risks through either excessive credit creation and asset bubbles during episodes of credit boom, or excessive cut back in credit during slumps. The basic reasoning behind such arguments is that credit supply matters. For example, a relaxation in lending standards may lead to excessive credit creation during booms and large losses to capital may generate a deleveraging cycle that wipes out good credit during busts.

The concern that malfunctions in the credit supply process may generate unnecessary crises leads to calls for large scale policy intervention in credit markets. For example, central banks are advised to "lean against the wind" if credit is expanding due to lax lending practices. On the other hand, central banks and governments are urged to inject liquidity and capital in the banking system if credit is being cut due to a deleveraging process.

This note seeks to answer the following question:

• What tools does a regulator or policy maker have at her disposal to judge whether changes in bank credit are driven by supply-side factors?<sup>1</sup>

The question is important because if change in bank credit were driven by genuine demand-side factors such as productivity shocks or shocks to expectations, then policy intervention based on the premise that the fault lies on the credit supply side can be counter productive. Moreover, even if supply-side factors influence bank credit, these factors may not be too relevant for the economy if there are sufficient new and alternative sources of financing to pick up any slack created by mis-performing banks.

I outline a methodology that can help policy makers better understand the extent to which supply side factors generate aggregate fluctuations in credit. The methodology is based on the regulator having access to a timely and comprehensive *credit registry* that contains information on every business loan given out by the banking sector. While such credit registry data are available in many countries around the world, the U.S. does not

<sup>&</sup>lt;sup>1</sup>My focus here is on commercial lending to firms. A related question corresponding to consumer financing is discussed by Amir Sufi in the article "Detecting Bad Leverage" in this volume.

currently have a comparable system. I discuss the design issues related to the building up a credit registry database in section 2. Section 3 outlines the methodology that can be applied to credit registry data to isolate the role of supply-side factors and section 4 provides real world examples. Section 5 concludes with a discussion of some of the limitations of the proposed methodology.

## 2 Credit Registry Design

I begin with a brief description of the design of credit registries (see World Bank 2011 for more details). There are four basic steps in the design of a credit registry system: data collection, data validation, data dissemination and data usage.

Data collection: Credit registry data are collected from every commercial borrower in the banking system. The data contain identification information on borrower and lender, and may include details such as name, location, industry and ownership information. Information on location, industry and ownership is particularly useful for testing if credit is concentrated in certain regions, industries, or groups of companies and whether such trends have strengthened over time. A typical credit registry records both positive and negative credit information. Positive credit information includes total amount of credit issued, credit outstanding, maturity, and collateral value (if any). Negative credit information includes default rate (broken by 30-day, 60-day, etc.), recovery in case of default and any legal actions against the borrower in the past. In certain countries there may be a sunset provision on negative information such that negative information is automatically deleted from the record after a pre-determined number of years. It is common for credit registry data to be updated on a monthly basis. With the advancements in information technology, collecting credit registry data at a monthly frequency is not too cumbersome.

Data validation: An important step after data collection is its validation to minimize errors. Automated routines can be set up to check if the data are coded appropriately and whether individual data items add up to the consolidated version. Any significant discrepancy found in the validation stage can be sent back to the data collection stage for

further verification. Random audits of loan level data are also useful in strengthening data quality and incentivizing data collectors to monitor the process appropriately. Such audits not only help keep the data quality high but also improve transparency and reliability of the banking sector financial data.

Data dissemination: Every credit registry data must have appropriately designed rules on how data will be disseminated and who can get access to the data. There is a fundamental tension between maintaining proprietarship of data and making data accessible to a wider audience. Banks that rely on "relationship banking" may want to keep their portfolio confidential to maximize leverage and rents in their relationship. Doing so may - in theory - also be optimal ex-ante to give incentives to banks to spend effort in adding first-time borrowers to the banking sector. However, such benefits of data proprietership must be weighed against the broader benefits of data sharing. These include enabling banks to get a real time sense of the overall exposure of their clients (and related parties) with other banks and allowing regulators / researchers quick access to data for macro prudential purposes (as explained in next sections).

Putting all this together, while it is important to create and share credit registry data, it is equally important to outline strict guidelines on who can access the data and how. It is imperative that everyone contributing to the credit registry data must have full confidence that the data will only be used for legitimate purposes.

Data Usage: Once a credit registry data is put in place, an obvious use of the data is to help regulators and the banking sector use the data for prudential and risk-management purposes. The rest of this note explains how the data can also be combined with more scientific empirical methodologies to better identify the fundamental drivers of credit boom and bust. The accumulated knowledge can then help policy makers make more informed choices.

## 3 Methodology

The methodology outlined here was introduced by Mian and Khwaja (2008) and augmented by Jimenez, Mian, Peydro and Saurina (2011). The basic purpose of the methodology is to test specific hypotheses about the role of supply-side factors in generating observed changes in bank credit. The methodology offers two advantages from an econometric standpoint. First, it provides an unbiased estimate of the supply-driven "bank lending channel" effect. Second, it takes into account general equilibrium adjustments made at the borrower level in reaction to the bank lending channel effect and provides a bias-corrected net effect of the bank lending channel at the borrower level. We briefly illustrate the methodology below.

Consider an economy with banks and firms indexed by i and j respectively. Firm j borrows from  $n_j$  banks at time t and assume that it borrows the same amount from each of the  $n_j$  banks. The economy experiences two shocks at t: a firm-specific credit demand shock  $\eta_j$  and a bank-specific credit supply shock  $\delta_i$ .  $\eta_j$  reflects changes in the firm's demand for credit driven by productivity or customer demand shocks.  $\delta_i$  reflects changes in the bank's funding situation, such as a run on short term liabilities (a negative shock), or new opportunities to access wholesale financing (a positive shock.)

Let  $y_{ij}$  denote the log change in credit from bank i to firm j. Then the basic credit channel equation in the face of credit supply and demand shocks can be written as:

$$y_{ij} = \alpha + \beta * \delta_i + \eta_j + \varepsilon_{ij} \tag{1}$$

Equation (1) assumes that the change in bank credit from bank i to firm j is determined by an economy wide secular trend  $\alpha$ , credit supply and credit demand shocks, and an idio-syncratic shock  $\varepsilon_{ij}$ . While equation (1) is reduced form in nature, it can be derived as an equilibrium condition by explicitly modeling credit supply and demand schedules.

In a frictionless world (as in the Modigliani-Miller theorem), bank lending is independent of credit supply conditions and only depends on "fundamental" credit demand factors. Financial intermediaries in such scenarios have no impact on the economy and, hence, there is no bank transmission channel, i.e.  $\beta = 0$  in equation (1). The presence of financing frictions,

however, may force banks to pass on their credit supply shocks  $\delta_i$  to borrowing firms, making  $\beta > 0$ .

 $\beta$  if often referred to as the "bank lending channel", and is the key supply-side parameter of interest.  $\beta$  can be estimated from (1) using OLS, giving us  $\widehat{\beta}_{OLS} = \beta + \frac{Cov(\delta_i, \eta_j)}{Var(\delta_i)}$ . The expression implies that as long as credit supply and demand shocks are significantly correlated,  $\widehat{\beta}_{OLS}$  in (1) would be a biased estimate of the true  $\beta$ . For example, if banks receiving a positive liquidity shock are more likely to lend to firms that simultaneously receive a positive credit demand boost, then  $\beta$  would be biased upwards. Khwaja and Mian (2008) resolve this issue by focusing on firms with  $n_j \geq 2$ , and absorbing out  $\eta_j$  through firm fixed-effects. The estimated coefficient  $\widehat{\beta}_{FE}$  then provides an unbiased estimate of  $\beta$ .

However,  $\widehat{\beta}_{FE}$  does not give us a complete picture of the net effect of bank lending channel on the economy. In particular, individual firms affected by the local lending channel due to a positive  $\beta$  in equation (1) may seek funding from new banking relationships to compensate for any loss of credit. Jimenez et al (2011) show that an unbiased estimate of the *net* (or aggregate) effect of supply-side banking shocks on borrower j can be estimating using the equation:

$$\overline{y}_j = \overline{\alpha} + \overline{\beta} * \overline{\delta}_j + \eta_j + \overline{\varepsilon}_j \tag{2}$$

where  $\overline{y}_j$  denotes the log change in credit for firm j across all banks.<sup>2</sup> It is not a simple average of  $y_{ij}$  from (1) since a firm can start borrowing from new banks as well.  $\overline{\delta}_j$  denotes the average banking sector shock experienced by firm j at time t, i.e.  $\overline{\delta}_j = \sum_{i \in N_j} \frac{\delta_i}{n_j}$ , where  $N_j$  represents the set of banks lending to firm j at time t.  $\overline{\varepsilon}_j$  is an idiosyncratic error term. The same credit demand shock  $\eta_j$  appears in both equations (1) and (2) under the assumption that the shock equally affects a firm's borrowing from all banks. The aggregate impact of credit supply channel is captured by the coefficient  $\overline{\beta}$ . If there is no adjustment at firm-level in the face of bank-specific credit channel shocks, then  $\overline{\beta} = \beta$ .

<sup>&</sup>lt;sup>2</sup>Depending on data availability, it could include non-bank sources of credit as well.

How does one estimate  $\overline{\beta}$ ? An OLS estimate of (2) yields  $\widehat{\overline{\beta}}_{OLS} = \overline{\beta} + \frac{Cov(\delta_i, \eta_j)}{Var(\overline{\delta_j})}$ . While the variance of  $\overline{\delta}_j$  can be estimated in data, the covariance term between credit demand and credit supply shocks is unobservable to the econometrician. However, a unique advantage of the preceding fixed-effects estimator at loan level is that it allows us to back-out the covariance term. Since  $\widehat{\beta}_{FE}$  is an unbiased estimate of  $\beta$ , we can write  $Cov(\delta_i, \eta_j) = (\widehat{\beta}_{OLS} - \widehat{\beta}_{FE}) * Var(\delta_i)$ , where variance of bank credit supply shocks  $\delta_i$  can be estimated directly from data. Thus the aggregate lending channel effect,  $\overline{\beta}$ , can be estimated as:

$$\widehat{\overline{\beta}} = \widehat{\overline{\beta}}_{OLS} - \left(\widehat{\beta}_{OLS} - \widehat{\beta}_{FE}\right) * \frac{Var(\delta_i)}{Var(\overline{\delta}_i)}$$
(3)

The second term on the right hand side of (3) is the adjustment term that corrects for any bias in the OLS estimate of (2). The adjustment term corrects for the otherwise unobserved covariance between credit supply and demand shocks. The extra variance term in the denominator corrects for the fact that the variance of bank shocks averaged at the firm level may be different from the variance of bank shocks overall.

A key advantage of the proposed methodology is that it can be implemented in real time. In particular, for any given bank shock  $\delta_i$  that is suspected of generating a transmission channel, run OLS and FE versions of (1) to estimate  $\hat{\beta}_{OLS}$  and  $\hat{\beta}_{FE}$  respectively. Then estimate firm level equation (2) using OLS to generate  $\hat{\beta}_{OLS}$ . Finally plug these three coefficients in (3) to estimate the unbiased impact of credit supply channel at the firm level.

A second advantage of the proposed procedure is that it relies on credit registry data which exists in most countries of the world with banking supervision departments. We next provide three examples of the use of this methodology from Pakistan, Spain and the United States.

<sup>&</sup>lt;sup>3</sup>This follows from the observation that  $Cov(\overline{\delta}_j,\eta_j)=Cov(\sum_{i\in N_j}\frac{\delta_i}{n_j},\eta_j)=Cov(\delta_i,\eta_j).$ 

## 4 Examples

#### 4.1 Nuclear Tests And Dollar Deposit Run On Banks In Pakistan

The unexpected nuclear tests by Pakistan in May 1998 imposed stiff sanctions on the country that led to a serious balance of payment crisis. Consequently the government defaulted on its obligation to pay back dollars that it had borrowed through the banking sector's "dollar deposit scheme". The default on dollar obligations led to a serious run by depositors on the banking sector. However the run was not uniform across banks, but concentrated on banks that were more reliant on dollar deposits as a funding source<sup>4</sup>.

Khwaja and Mian (2008) evaluate the credit supply consequences of the run on bank deposits. We estimate equation (1) with borrower fixed effects separately for each quarter t.  $y_{ij}$  is defined as log change in loan from bank i to firm j. The change is computed from the quarter prior to the nuclear tests till quarter t.  $\delta_i$  is defined as the log change in deposits for bank i in the aftermath of the nuclear tests.

The set of estimated coefficients  $\widehat{\beta}_{FE,t}$  (one for each t), trace out the supply side impact of the run on deposits. Each coefficient  $\widehat{\beta}_{FE,t}$  is computed using the within-firm difference in loan growth from banks with (relatively) high deposit growth versus banks with low deposit growth. Figure 1 plots this difference after classifying above and below median deposit growth as "positive" and "negative" liquidity shocks respectively.

There is no sign of a credit supply effect until the nuclear shock hits. Following the nuclear tests, we see a strong credit supply effect from the run on deposits. While there is a strong credit supply shock at the loan level, Mian and Khwaja (2008) show that this effect is completely neutralized by large firms (top 30% of firms by size) as they are able to borrow from new sources of funding. Thus the credit supply shock ends up affecting only smaller firms. Such an analysis can help policy makers understand the magnitude of the credit supply shock, and isolate the set of firms most in need of additional credit support.

<sup>&</sup>lt;sup>4</sup>Banks could not hold these dollar deposits themselves. They turned over the dollar deposits to the central bank in exchange for equivalent rupees under the promise that the central bank would return dollars on demand from the depositor.

#### 4.2 Real Estate Securitization And Bank Credit In Spain

Jimenez et al (2011) apply the methodology above to the case of Spain and test whether the boom in real estate securitization during the 2000's enabled banks with large real estate assets to expand credit supply by securitizing their real estate portfolio. They estimate equation (1) with borrower fixed effects separately for each quarter t.  $y_{ij}$  is defined as log change in loan from bank i to firm j. The change is computed from 2004Q4 till quarter t.  $\delta_i$  is defined as the ex-ante (year 2000) variation in real estate holdings for bank i. Real estate exposure proxies for the capacity of banks to securitize assets during the securitization boom. The analysis utilizes a comprehensive quarterly loan level credit registry data from the Bank of Spain that covers a period from 1999Q4 to 2009Q4.

Figure 2 plots the firm fixed effect estimate of the credit supply effect of real estate exposure,  $\hat{\beta}_{FE,t}$ . Starting 2004 (when securitization in Spain shoots up), there is a strong positive credit supply effect for banks with real estate exposure due to improved access to wholesale financing. The positive credit-supply effect turns negative in 2008 however as global securitization market shuts down.

Jimenez et al (2011) show that despite a significant loan-level credit supply effect, the net (aggregate) impact of securitization at the borrower level is muted due to a "crowding out" effect. Nonetheles there is a significant aggregate impact of the expansion in credit supply on the price of credit. Securitization also leads to a reduction in loan collateralization rates and lengthens maturity of loans.

#### 4.3 U.S. Financial Crisis And Bank Credit Lines

Some observers argue that a reduction in the supply of credit to corporations was an important factor in precipitating the economic downturn during 2007-08. Ivashina and Sharfstein (2010) show that corporations drew down on their lines of credit significantly during this period, and especially more so from banks experiencing larger losses and thus under greater threat of going bankrupt. One interpretation of this evidence is that there was a "run" by corporations on weak banks under the fear that future credit supply may be choked off.

However, in a recent paper using loan level data from the Fed's SNC program Mian and

Santos (2011) show that the increase in drawn lines of credit is not unique to the 2007-09 crisis. The same pattern is seen in each of the previous two recessions of 1990-91 and 2001 as well, and there was no banking crisis in 2001. Thus an alternative demand-based explanation for the increase in draw-down ratio is that as the economy slows, firms draw down as much as they can before their credit worthiness deteriorates.

We can use the methodology above to test if the corporate run on undrawn lines of credit was driven by credit supply shock. Using loan level data on syndicate loans from the Fed, we estimate equation (1), with  $y_{ij}$  defined as change in draw down percentage of a syndicate loan from lead-bank i to firm j.  $\delta_i$  captures the exposure of a lead bank to the crisis, which we proxy using bank's ultimate charge-offs to assets. We also add the initial level of draw-down percentage on the right hand side since the change in draw down is mechanically related to the initial draw down percentage.

While simple OLS estimation of (1) over 2006-07 and 2007-08 shows that banks with larger ultimate losses experience larger increase in draw-down percentage, this result is entirely driven by less credit worthy firms more likely to borrow from banks with greater exposure to the crisis. The unbiased borrower fixed effect estimate  $\hat{\beta}_{FE}$  is no longer positive with reasonably small standard errors. Thus the correlation between bank losses and increase in borrower draw down ratio is driven by the endogenous matching of firms with low credit worthiness to banks that end up experiencing large losses.

## 5 Concluding Discussion

Most concerns about systemic risk relating to the banking industry are based on the premise that bank credit supply may get out of whack with economic fundamentals. This note outlined a methodology that can be used to test specific hypotheses about the extent to which changes in credit are driven by supply-side factors. The methodology uses loan level credit registry data that are increasingly available in many countries. However, surprisingly the U.S. lags behind in the availability of detailed loan-level data. Ideally one would like to have loan-level data that covers the entire banking sector, and follows not just loan quantities

but also price terms such as interest rate, maturity, collateralization rate and basic covenants.

While I discussed three examples relating to my own work, other scholars have also used the methodolog highlighted here in conjunction with credit registry data to isolate credit suply effects. These include Cetorelli and Goldberg (forthcoming) on international transmission of credit supply shocks during 2007-08, Lin and Paravisini (2010) on the credit supply effect of bank reputation in the U.S., Paravisini (2008) on credit supply effects in Argentina, Jimenez, Ongena, Peydro and Saurina (2010, forthcoming) on credit supply effects of monetary policy in Spain, and Schnabl (forthcoming) on the international transmission of credit supply shocks in Peru.

I end with some caveats regarding the use of this methodology in practice. First, the use of credit registry data is feasible at a monthly or quarterly frequency only. Thus analysis of the sort discussed in this paper is more suitable for low frequency analysis.

Second, the methodology is based on a cross-sectional comparison of changes in loans over time, and may be viewed as a specific version of the difference-in-differences approach. As such the methodology is useful to the extent there are legitimate reasons to believe that the impact of credit supply is not uniform across all banks.

Third, the methodology by design limits the analysis to borrowers with multiple banking relationships. There is thus a concern that single relationship borrowers that may be most adversely impacted by credit supply shocks are left out. However, more than three quarters of bank lending often goes to borrowers with multiple relationships. Moreover, variation within multiple relationship firms can also be used to test if credit supply shocks affect smaller firms differentially.
